1. INTRODUCTION

1.1. Scope

This recommended practice (RP) of AACE® International (AACE) defines general practices and considerations for integrated cost and schedule risk analysis and estimating contingency using a combination or hybrid of estimate ranging and integrated cost and schedule expected value analysis with Monte Carlo simulation methods. R+EV is used as a shorthand designation for this quantitative risk analysis (QRA) combination. The base methods are covered separately in:

- RP 118R-21, *Risk Analysis and Contingency Determination Using Estimate Ranging for Inherent Risk with Monte Carlo Simulation* [1],
- RP 65R-11 *Integrated Cost and Schedule Risk Analysis and Contingency Determination Using Expected Value* [2].
 - Note: RP 65R-11, incorporates methods from RP 44R-08, *Risk Analysis and Contingency Determination Using Expected Value* for cost [3].

Those RPs should be reviewed for details of the respective methods; this RP is focused on how to use them in combination. Descriptions of other recommended risk quantification practices can be found in AACE Professional Guidance Document PGD-02, *Guide to Quantitative Risk Analysis* [4].

The R+EV method is a fit-for-use, practical, risk-driven method intended to support management’s need for integrated distributions of bottom-line project cost and schedule outcomes. It is intended to support investment or tender decision making for well-defined, relatively simple, low-technology projects at the sanction or tender phase (i.e., Class 3 or better estimates). See Professional Guidance Document PGD-01, *Guide to Cost Estimate Classification* for more information on Classification [5].

This method is not recommended for projects with significant systemic risks including projects at early scope definition phases (Class 10, 5 or 4) or with significant complexity, and/or with significant levels of technology. Complexity can result in non-linear behaviors not usually captured by estimate ranging and can also result in large numbers of minor risk events that together are significant but are not usually quantified in either ranging or expected value methods. This exclusion from usage results from the estimate ranging method’s limitations (i.e., RP 118R-21). For Class 4 or better definition, hybrid methods combined with parametric modeling are recommended when there are significant systemic risks; refer to either:

- RP 113R-21, *Risk Analysis and Contingency Determination Using Combined Parametric and Expected Value* [6] or
- RP 117R-21, *Integrated Cost and Schedule Risk Analysis and Contingency Determination Using a Hybrid Parametric and CPM Method* [7].

For Class 10 or 5 definition, where systemic risks are dominant, the parametric method, used alone, is recommended (i.e., RP 42R-08 *Risk Analysis and Contingency Determination Using Parametric Estimating* [8]).

While this method can provide limited insight of risks to some activities or milestones, this method is not recommended for projects needing to understand schedule risk at a detailed level (i.e., more detailed than just the completion date) such as the impact of risk on specific schedule activities or on intermediate milestones (these projects also tend to be more complex). This exclusion from usage results from expected value method limitations in regard to schedule (i.e., RP 65R-11). For detailed scheduling needs, QRA methods employing the risk-driven critical path schedule method (CPM) are recommended including:

- RP 57R-09 *Integrated Cost and Schedule Risk Analysis using Risk Drivers and Monte Carlo Simulation of a CPM Model* [9] or

February 23, 2022

- 70 • RP 117R-21, Integrated Cost and Schedule Risk Analysis and Contingency Determination Using a Hybrid
71 Parametric and CPM Method [7].
72

73 The method also excludes quantification of escalation risks (see RP 68R-11: *Escalation Estimating Using Indices and*
74 *Monte Carlo Simulation* [10]).
75

76 1.2. Purpose

77

78 This RP is intended to provide guidelines, not a standard, for contingency estimating that most practitioners would
79 consider to be good practices that can be relied on and that they would recommend be considered for use where
80 applicable. There is a range of useful risk analysis and contingency estimating methodologies; this RP, combined with
81 other QRA RPs outlined in PGD-02, will help guide practitioners in developing or selecting appropriate methods for
82 their situation.
83

84 It is an AACE recommendation that whenever the term *risk* is used, that the term's meaning be clearly defined for
85 the purpose of the practice. This hybrid method is intended to quantify two types of risks for cost and schedule:
86 *inherent* and *critical project-specific* risks. It is not intended for *systemic* risks when they are significant (i.e., when
87 the systemic risks are much greater than the inherent risks).
88

89 Inherent Risks-General:

90 RP 10S-90, *Cost Engineering Terminology* definition of inherent risk is "A risk that exists (but may or may not be
91 identified) due to the very nature of the asset, project, task, element, or situation being considered [11]. A similar
92 10S-90 term that could be said to apply is *background risks* which is defined as "A set of non-event risks specific to
93 the risk quantification method which cause variability for which probability of occurrence is 100%. When using a
94 particular method, the limited specific uncertainty must be communicated". For specificity then, a third definition
95 in 10S-90 for *background variability* may be most applicable (this is found as one of three alternate definitions for
96 the general term *uncertainty*). That definition states that background variability is uncertainty that is "distinct from
97 the variation caused by identifiable risks, that is caused by *at least* three commonly-found factors in projects; (a)
98 inherent variability of the work not caused by identified risks, (b) estimating error and error of prediction, and (c)
99 bias in estimating or prediction."
100

101 Inherent Risks-Duration:

102 The estimate ranging method in RP 118R-21 quantifies the cost impact of *inherent* risk. However, there is no RP with
103 equivalent detailed mechanisms for deriving duration impact values for inherent risks. No AACE references of any
104 kind were identified for doing this. RP 32R-04 *Determining Activity Durations* [12] speaks of and the CPM-based QRA
105 RPs 57R-09 and 117R-21 incorporate inherent risk duration impacts as 3-point ranges. However, the only methods
106 defined for deriving the values of the range are general statements that they can be obtained from workshops,
107 interviews and/or from the analysis of historical data. Therefore, this RP incorporates inherent risk duration impacts
108 using the same general approach; i.e., a 3-point distribution with values derived from workshops, interviews and/or
109 from historical data analysis.
110

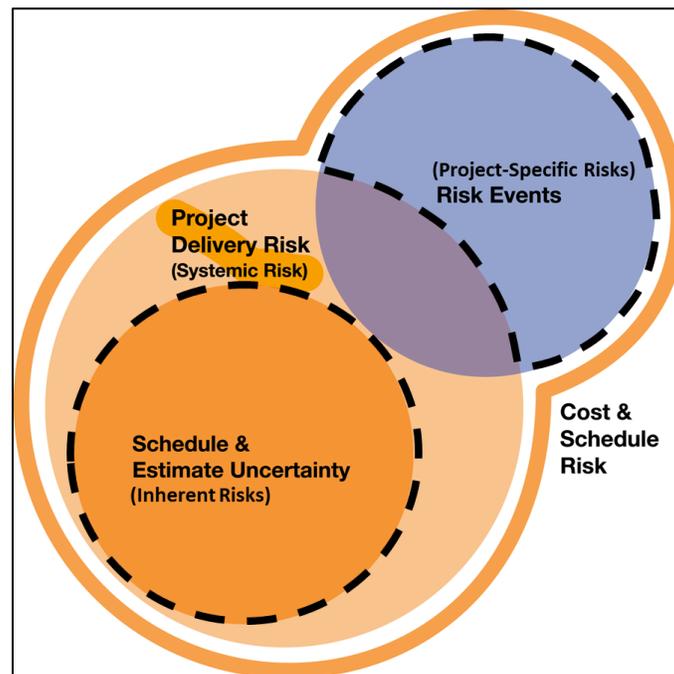

111 Project-Specific Risks:

112 The expected value method in RP 65R-11 quantifies the cost and schedule impact of *project-specific* risks. The 10S-
113 90 definition of project specific risk is "uncertainties (threats or opportunities) related to events, actions, and other
114 conditions that are specific to the scope of a project. (e.g., weather, soil conditions, etc.). The impacts of project-
115 specific risks are more or less unique to a project." They primarily consist of risk events (i.e., probability of occurrence
116 of less than 100%), but also include project-specific condition uncertainties (probability of occurrence is 100%; such
117 as significant variability in weather impacts or soil conditions). These risks are specifically identifiable and commonly
118 included in risk registers.

119
120 Systemic Risks (not covered):

121 As was stated this hybrid method is not recommended for projects with significant *systemic* risks. RP 10S-90 defines
122 systemic risk as “uncertainties (threats or opportunities) that are an artifact of an industry, company or project
123 system, culture, strategy, complexity, technology, or similar over-arching characteristics.” This encompasses
124 inherent risks, but is broader. The historical data analysis used for parametric modeling of systemic risks captures
125 the impacts of a wide spectrum of uncertainties that extend to the overall project system’s interaction with external
126 systems, uncertainty causes such as the level of complexity and technology, but also the nominal impacts of minor,
127 non-critical risk events which often fall off the risk management radar.

128
129 Figure 1 uses a Venn diagram to illustrate the concepts of inherent risks and *critical* project-specific risks (mostly risk
130 events but also condition uncertainties). The dashed line encompasses risks covered by this RP. Note that if systemic
131 risks are not significant, and the number of minor risk events is insignificant (i.e., limitations for using this RP), then
132 systemic risks become roughly analogous to inherent risk and the dashed inherent and project-specific pieces
133 converge to essentially cover all the risks on these simpler, well-defined projects.
134

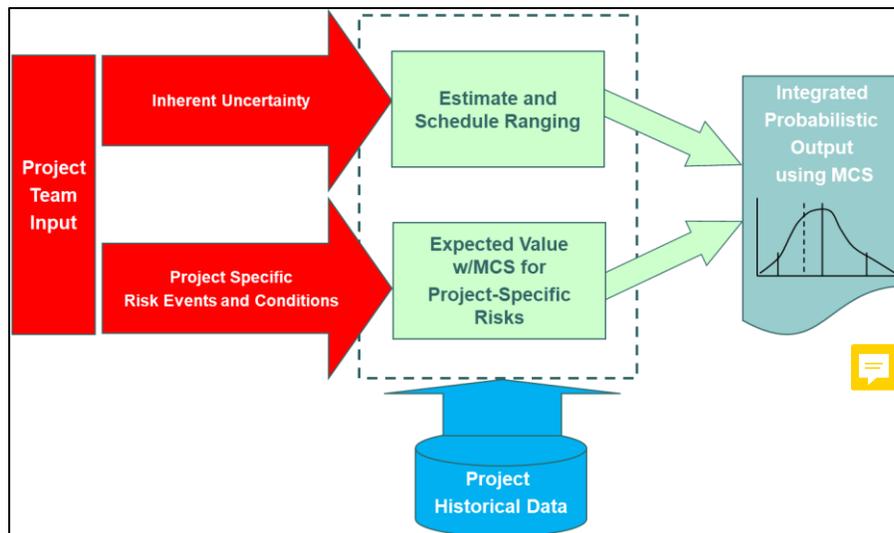

135
136 **Figure 1 – Inherent and Critical Project-Specific Risks Covered by this RP**

137
138 **1.3. Background**

139
140 The integrated, hybrid cost and schedule risk quantification method covered by this RP combines estimate and
141 schedule ranging of inherent risks and expected value with Monte-Carlo simulation (EV w/MCS) modeling of project-
142 specific risks. R+EV is used as a shorthand designation for the combination. The component methods are addressed
143 in RPs 118R-21 (plus the description of duration ranging herein) and 65R-11 respectively. Two methods are combined
144 because no single method is optimal for quantifying both inherent and project-specific risks when scope is well
145 defined (i.e., Class 3 or better). MCS is used in both the ranging and EV methods and to integrate the analyses
146 results. MCS is needed for the combination because only the mean values of the individual method outputs are
147 additive (e.g., the overall cost or duration at say p70 confidence level is not the sum of the separate analyses p70
148 values). Figure 2 illustrates the hybrid concept:

149

150

171

In the EV method as defined in RP 65R-11, only *critical* project-specific risks are quantified; i.e., those with the potential of creating significant impacts on project success in terms of cost and/or schedule and ultimately profit or other general outcomes (the criteria for a risk being identified as “critical” are defined in RP 65R-11). Most risks in a risk register will not meet these criteria. For these critical risks, the quantitative analysis will first assure that the nature of the risk is well understood (e.g., is the root cause understood, has too much credit been taken for mitigation efficacy, etc.?), and the probability of occurrence and their impact will be reviewed; i.e., the information in a risk register should not be accepted or used verbatim.

Inherent risks by definition are generally not identifiable as to a specific cause; i.e., it is background variability. For this risk type, estimate and duration ranging are applied. The typical quantitative analysis challenge with ranging is that often there is limited historical data to inform the analysis, putting the onus on subjective team inputs from workshops or interviews. Subjective inputs are always subject to bias (optimistic or pessimistic), which, if not effectively managed by the workshop facilitator can greatly distort outcomes. Optimally, a robust historical database is available to provide applicable range metric information (re: RP 114-20 *Project Historical Database Development* [13]). Estimate ranging methods (i.e., 118R-21) attempt to dissect the sources of estimate variability (e.g., contributions of quantity versus rate uncertainty, etc.) providing some assurance that the range is well understood. Duration ranging has no such documented methods. In either case, the quality of the result is highly dependent on the skills and knowledge of the facilitator.

The hybrid approach in this RP results in an integrated cost and schedule analysis; i.e., it generates both project cost and overall duration distributions. The cost and duration inherent risk can be correlated in the MCS model, and the EV method correlates cost and schedule impacts based on the risk response(s) assessed for each critical risk. Being integrated, a joint confidence level (JCL) determination can be made.

176

177

2. RECOMMENDED PRACTICE

178

179

180

2.1. Hybrid Application Steps

181

182

As discussed, RPs 118R-21, 44R-08 and 65R-11 must be reviewed for background and details of each of the underlying methods. RPs 32R-04, 57R-08 and 117R-21 can be reviewed in respect to their discussions of inherent

February 23, 2022

183 duration uncertainty ranging (although the treatment is limited). This is not a stand-alone RP. The following describes
184 the steps of implementing the R+EV hybrid method.

185
186 Precursor-Tools

187 The steps of this process assume that tools are in place for 1) estimate ranging of inherent risk and 2) for expected
188 value analysis with MCS for project-specific risks. A tool that pulls these together, and that adds duration ranging of
189 inherent risks will be needed as well. The tools, for each risk type and overall, are typically custom Excel-based
190 worksheets using an MCS add-on. It is possible to implement basic MCS in Excel without an add-on, but it tends to
191 be cumbersome and offers limited risk analysis capabilities (e.g., dependencies are difficult to model).

192
193 The examples in Section 2.2 provide more information on typical tools. Note that the method described is quantifying
194 the distribution of cost growth and schedule (duration) slip resulting from the risk drivers. These define the
195 contingency contributions. The overall project cost distribution is then the sum of the base cost and duration
196 estimate values and these distributions. With the tools in place, the steps in applying them as a hybrid application
197 are as follows:

198
199 Step 1: Per RP 118R-21; Apply Estimate Ranging Model for Inherent Risk

200 Assess and quantify the cost ranges (usually 3-point distributions at various levels of estimate breakdown) of the
201 estimate elements as appropriate and enter them in the estimate ranging model. Note that the examples in RP 118R-
202 21 model total cost as the final output. For the hybrid model, modify the ranging model output to generate the cost
203 growth which is the resulting total cost distribution minus the base cost estimate value. For the hybrid model, only
204 this cost growth output distribution will be carried forward as an input to the overall MCS model (with correlation
205 to the duration uncertainty per Step 3).

206
207 Step 2: Determine Overall Project Duration Distribution for Inherent Risk

208 Quantify the inherent duration uncertainty for the overall project from the start to the completion milestone. This
209 is typically a 3-point estimate (low, most likely, high or L/ML/H) with an associated 3-point probability distribution
210 function (PDF). The inputs to the distribution will be obtained from a workshop and/or interviews, optimally
211 supported by historical data analysis of duration ranges for similar projects (after adjusting the historical metrics to
212 deduct an allowance for the schedule impact of known critical risk events). The historical data analysis must attempt
213 to isolate the impact of the inherent duration uncertainty; and disregard the schedule impact from known critical
214 risk events.

215
216 This distribution entry can be added as a separate element to the bottom of an estimate ranging worksheet in order
217 to support an integrated hybrid application. The L/ML/H duration values can be entered as risk factors (e.g., 0.90,
218 1.05, 1.20) for which the result, after MCS, will be multiplied times the base duration (e.g., 1.05 times 20 months) or
219 duration uncertainty can be modeled as direct overall duration values (e.g., 18, 21 and 24 months). As with the
220 estimate ranging model, add a calculation to determine the schedule slip which is the total duration distribution
221 minus the base duration estimate value. For the hybrid model, only this schedule slip output distribution will be
222 carried forward as an input to the overall MCS model (with correlation to the cost uncertainty per Step 3).

223
224 Step 3: Quantify the Inherent Cost and Duration Distributions Correlation

225 The hybrid model must apply a correlation coefficient(s) between the inherent cost and duration distributions for
226 MCS from Steps 1 and 2. A key driver of inherent risk uncertainty is bias in the base estimate and schedule and the
227 respective biases tend to drive the uncertainty correlation factors. For example, consider the case where a large high
228 range was assigned to the cost distribution to reflect the team's opinion that the quantities are understated for a
229 generally aggressive base estimate. In that case, if an MCS iteration samples the cost distribution at this high end
230 (implying more quantity than estimated), then arguably the MCS sampling of the duration estimate should also lean
231 to its high end (i.e., it takes more time to install additional quantity indicating a strong correlation), especially if the

February 23, 2022

232 base schedule was also generally aggressive. However, what if the scheduler, working independently, had a
233 conservative bias and padded their base durations? In that case, estimate and schedule development are more
234 independent (not a good practice) and the correlations will be weaker.

235
236 Determining correlation coefficients is challenging in the best of circumstances. Typically (as described in RP 118R-
237 21), the inputs about inherent cost and duration correlations will be qualitative (e.g., high, moderate, low
238 correlation) and the analyst will need to translate these into quantitative values for the model. General rules such
239 as 0.75, 0.5 and 0.25 for high, moderate, low correlations may be used (although negative correlations are possible);
240 more scientific methods for inherent risk are usually not justified. The important point is to address correlation
241 through looking at how integrated the estimate and schedule development process was (the more integrated, the
242 more correlated) and their relative biases (the more that the bias is directionally the same, the more correlated). A
243 conservative approach (because more correlation adds more span to outcome distributions) is to start with all
244 correlations being set to 1.00 (i.e., assuming a highly integrated estimating/scheduling process) and then only
245 reducing the correlation when there is a valid reason. Alternatively, when knowledge of the estimating process is
246 less, a correlation coefficient of 0.5 is suggested as a reasonable rule of thumb¹.

247
248 Note that there will be a temptation to add a separate time-dependent cost allowance to the duration uncertainty
249 outcome; however, with appropriate correlations, as schedule varies to the high side, so too will costs and vice-
250 versa.

251
252 Step 4: Per RP 44R-08; Screen the Risk Register and Identify Critical Risks
253 Optimally, the risk register will already have categorized each risk by quantification method type to be applied (i.e.,
254 create a column in the risk register to identify if the risk is systemic, project-specific, escalation or currency). This
255 categorization can be a challenge because the individual risks in a register are often not well titled or described as
256 to their nature and cause. In general, the more ambiguous, or the more the risk is in the nature of a worry or an
257 issue, the greater the likelihood a risk is inherent or systemic.

258
259 Further screen the project-specific risks to develop a list of those that are *critical* and refine the descriptions of their
260 nature and cause. The definition of critical risks is included in RP 44R-08, but in general these are risks that have a
261 material impact on the project economics. Risks are selected based on their post treatment, residual status. Check
262 for any risks that were critical pre-treatment, but non-critical after mitigation; assure that the risk reduction credited
263 to the mitigation is realistic. Post treatment, there should typically be no more than 5 to 15 critical risks, keeping in
264 mind that by definition any one critical risk will put the project success at risk. Having too large a number of truly
265 critical risks implies that the project may not be viable. Note that escalation and currency risks are not covered in
266 this RP (see RP 68R-11).

267
268 Step 5: Per RP 44R-08; Quantify the Probabilities of Occurrence
269 Capture the critical risk titles and clear description in the EV tool (do not link to the risk register; start fresh). Assess
270 and input the percent probability of occurrence for each critical risk (again, this is post-treatment residual risk).
271 Probability can be treated as a distribution depending on the team's confidence in their assessment as discussed in
272 RP 44R-08. Establish any dependencies between the risks (or combine risks if they are similar in nature), again as
273 discussed in RP 44R-08 and/or 65R-11.

274
275 Step 6: Per RP 65R-11; Quantify the Burn Rates
276 The *burn rate* is the approximate spending per month (or other period used) during the anticipated delay duration.
277 This typically includes direct field labor, indirect costs (e.g., temporary facilities, general services), and owner and

¹ The Rand Corporation research referenced in RP 42R-11 found a correlation coefficient of 0.41 between cost growth and schedule slip outcomes [8]

February 23, 2022

278 contractor project and construction management. Burn rate can be estimated on a case-by-case basis or pre-
279 determined for project contracts (e.g., site preparation) or phases. These burn rate estimates are generally Class 5
280 in quality realizing that cash flow can vary widely, some portion of the labor may be productively employed on other
281 activities, and so on. Optionally, the burn rate(s) could be entered as a 3-point distribution in MCS.
282

283 Step 7: Per RP 65R-11; Plan the Risk Responses

284 Determine and document the assumed or planned risk response (i.e., the contingency or contingent plan). Note that
285 this response is the ex-poste action(s) the team will take if and when the risk occurs. It is not a treatment or
286 mitigation (hence the term treatment and response are separate and unique in this methodology). The response in
287 large part defines the scope of the impact estimates. For example, if the project is schedule-driven, money may be
288 no object (within reason) to the business in order to recover the schedule; so, a fast/costly risk response is defined.
289 If management is unsure as to the response, then the impact estimates in the next step will have a correspondingly
290 wide range to cover the various response possibilities.
291

292 Step 8: Per RP 65R-11; Quantify the Schedule and Cost Impacts

293 Estimate and input the schedule and cost impacts of each critical risk. These are typically 3-point estimates with an
294 associated 3-point probability distribution function (PDF). The impact estimates reflect the risk response(s)
295 anticipated, i.e., the risk response largely defines the scope of the impact estimate.
296

297 For schedule, the duration impact, considering the risk response, is to the completion milestone. As described in RP
298 65R-11, team knowledge of what is on or near the critical path and the network's general, dynamic behavior is
299 needed. If confidence is low in understanding of the impact to the completion date, this should be reflected in the
300 range of the 3-point delay estimate.
301

302 For cost, the impact is a combination of time-dependent costs for schedule delays plus the non-time driven cost
303 considering the risk response. The time-dependent cost is the schedule delay times the applicable burn rate from
304 Step 6. The non-time dependent cost is the range of potential expenditures considering the risk response.
305

306 The EV tool must be set up to perform the calculation of the EV of the cost and of the schedule duration impact of
307 each risk (i.e., probability times impact). In MCS, the simulation results for each risk, or subtotal of several risks, can
308 be captured independently if desired. This subtotal result can be used to assess the impact on intermediate
309 milestones if one or more of the risks drive that milestone (see RP 65R-11).
310

311 Step 9: This RP; Integrate the Ranging Outputs into the EV Model (this creates the hybrid)

312 To integrate the cost and duration ranging results with the EV results, include "inherent risk" and its cost growth and
313 schedule slip output distributions (re: Step 1 to 3) as the first critical risk in the EV w/MCS tool. The probability of
314 occurrence of the inherent risk is 100 percent per the definition of inherent risk. Inherent risks are treated as
315 independent of the project-specific risks for this method.
316

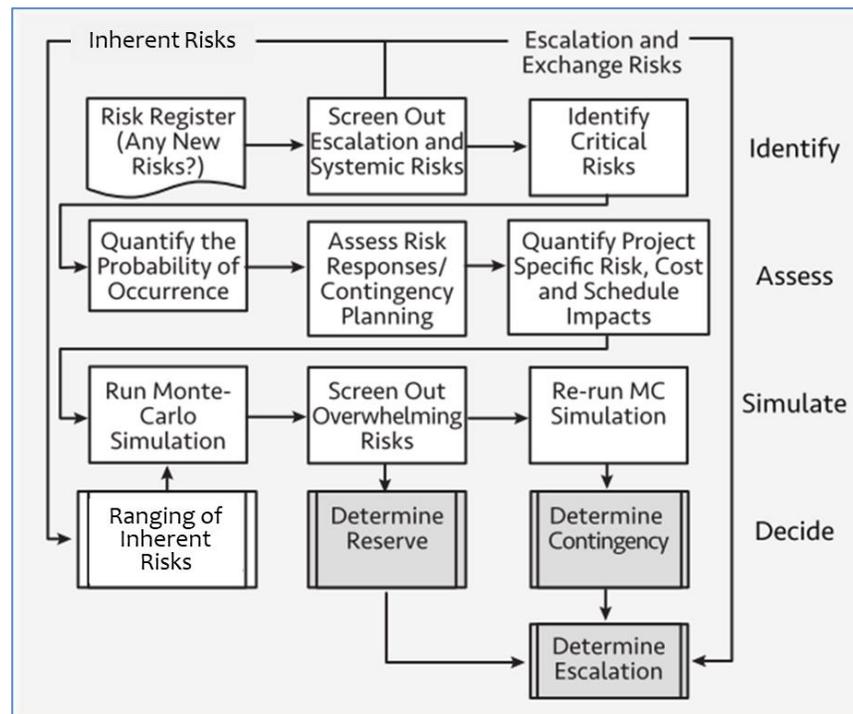

317 Step 10: This RP; Run the R+EV MCS Simulation

318 The R+EV tool must be set up to sum all of the cost (cost growth) and duration (schedule slip) impacts for the inherent
319 and critical project-specific risks. Running the MCS will generate the overall distributions of these risk sums (plus any
320 subtotal that were defined as MCS outputs).
321

322 Adding the base cost and duration estimates to the risk outputs will provide the overall cost and schedule
323 distributions. From the total distributions, determine the overall cost and schedule contingency (and reserves if
324 appropriate) based on risk policy or management's risk tolerance. The cost and schedule results are integrated since
325 there is correlation between the inherent cost and duration outcomes and the project-specific risk impacts in the EV
326 method are based on assumed risk responses that consider cost/schedule trading.

327
328
329
330
331
332

Figure 3 summarizes the hybrid R+EV application in flow chart format. Note the input of ranging inherent risks into the EV w/MCS model is shown in the bottom row. Escalation is not included in the R+EV method but is shown here to illustrate that the cost and schedule distributions can be used as inputs to a probabilistic escalation tool (re: RP 68R-11).

333
334

2.2. Hybrid Tool Example

337

This section provides an example of a combined R+EV toolset and illustrates the analysis steps applied in a tool. The toolset shown in the example figures are stylized for the RP, but are based on working tools.

339

340

2.2.1. Cost and Duration Estimate Ranging Model

341

342

Figure 4 is an example inputs table for an estimate ranging worksheet in Excel®. This is taken from RP 118R-21 (with the addition of duration ranging). This example, and Figure 4, are derived from an engineering, procurement and construction (EPC) contractor analysis of cost and duration estimating inherent uncertainty, used as input to an overall hybrid project QRA that adds analysis of critical project-specific risks.

344

345

346

347

RP 118R-21 describes this example in more detail including comments on its strengths and weaknesses. However, in summary, the example applies estimate ranging at the summary level of a process plant cost estimate that has been broken down by direct (including labor and material categories) and indirect accounts at a discipline level. Duration is entered as the total number of months. In this example, the approach was to multiply probabilistic “range factors” (in this case 3-point distributions) times various cost elements and summing the products. The same is done for overall duration. Using an MCS add-on, the distributions of each individual factor x cost, the subtotals and the total cost are obtained for reporting. The same is done for the duration distribution (i.e., duration factor x duration).

Cost. Duration and Range Factor Inputs

The table labeled “A” on the left side of Figure 4 shows the estimate summary. This table is all inputs and summations; there are no MCS formulae. The worksheet simply sums the direct cost elements to get the direct line-item totals, and then adds the indirect item costs to get various subtotals and the total cost. The direct cost elements (in color) that will be multiplied by range factors are the Labor, Equipment, Bulk Materials and Sub-Contracts cost entries plus the line-item costs entered in the Indirect Cost section. Note that the columns labeled Quantity, Man-Hours and Labor Rate are not used in the model (they were likely shown to match the estimate basis report).

The table labeled “B” on the right of Figure 4 shows the range factor or multiplier inputs for use in trigen distributions. A range factor of 1.00 (or 100% as shown in Figure 4) has no effect on the cost. Trigen is a 3-point distribution requiring a low, most likely, and high input (L/ML/H). This model uses a multiplier of cost rather than entering cost directly as a 3-point range. Another common approach is to enter high/low +/- percentages of the base estimate with 0% often assumed for most likely (an unbiased base estimate); the percentages are applied as factors so the outcome is the same. Note that in this case, the “most likely” factor used was not always 1.00; implying that the team is recognizing the base estimate is somewhat aggressive. Table B is also all inputs; there are no MCS formulae here.

The table labeled “C” on the bottom of Figure 4 shows the base duration entry (in this case execution duration from sanction through mechanical completion) and the range factor inputs for use in trigen duration distributions. The comments regarding table B ranges also apply here.

Figure 4 – Example Cost and Duration Model Inputs for Inherent Risks

MCS Distribution Application

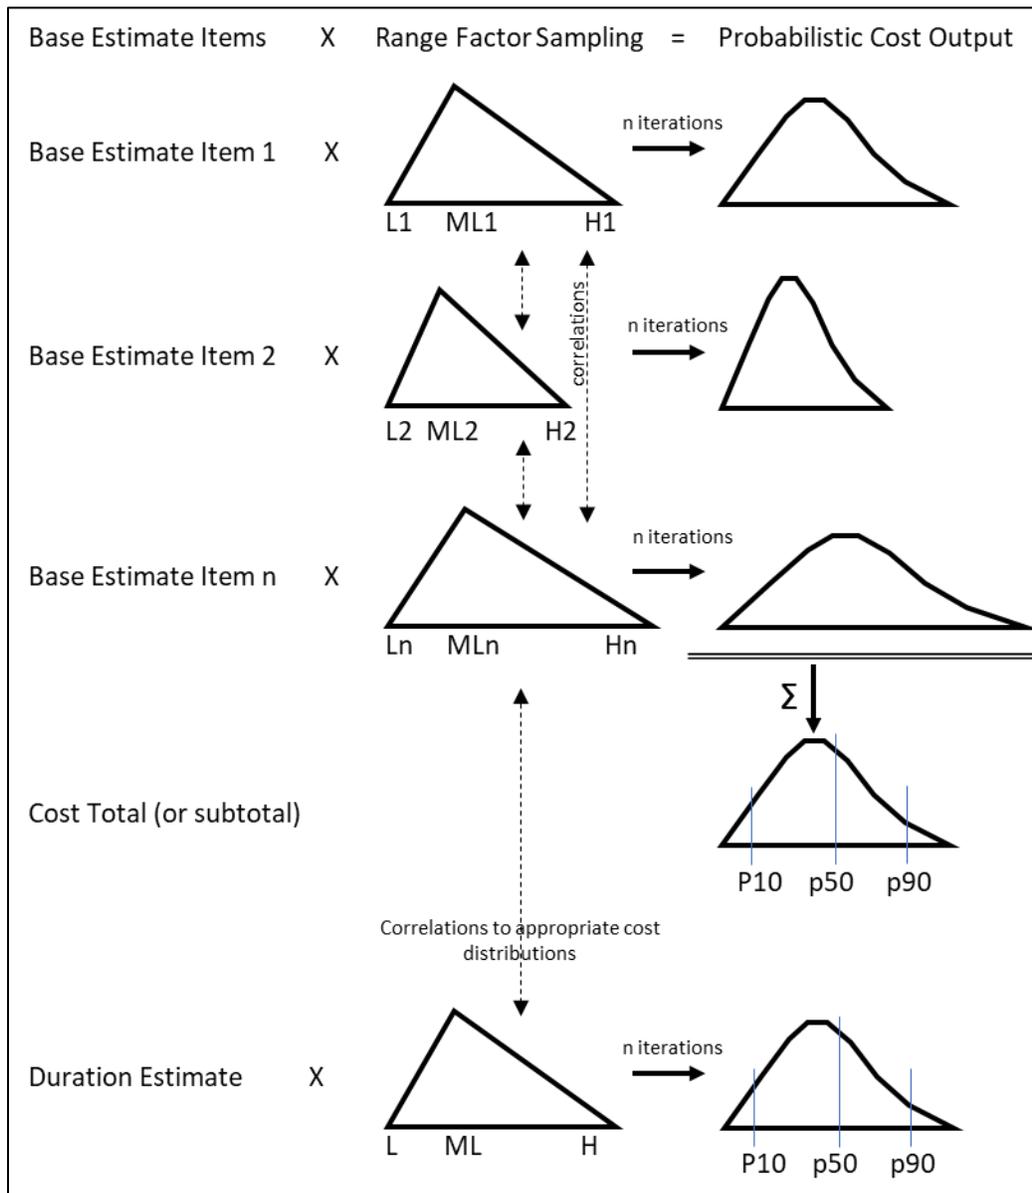

Note that this RP (and other QRA RPs involving MCS) expects users to have basic familiarity with applying MCS. The

February 23, 2022

382 details of defining distributions and dependencies are not covered here. Also, it is difficult to illustrate MCS
383 application, which largely takes place within spreadsheet formulae with software-specific terms, so the example's
384 MCS approach is described narratively.

385
386 The general MCS approach as shown in Figure 5 was to multiply probabilistic range factors times the respective cost
387 and duration inputs as were shown in Figure 4. For example, Equipment cost was multiplied by a range factor applied
388 as a trigen distribution with input low, most likely and high factors of 1.00, 1.00 and 1.28. When the MCS simulation
389 is run, the add-on will iteratively sample (e.g., say 10,000 iterations) from this range factor distribution, multiply it
390 by the Equipment cost, and hence derive and store a dataset of resultant products of factors x cost for Equipment.
391 These factor x cost products for various elements are then subtotaled and then finally grand totaled, and each total
392 can also be named, stored and reported as outputs by the MCS application.

393
394 Figure 5 also shows at the bottom that duration uncertainty was quantified in a similar manner with the only
395 connection to cost being defined correlation coefficients between the duration and appropriate cost element range
396 factor distributions.
397

398
399

Figure 5. Illustration of the Example MCS Application by Cost Item and for Duration Using Range Factors

400 The total cost and duration distributions will typically be of most interest to management; it is used to decide on
 401 contingency values. For example, if management decides (or if it is company policy) to fund contingency at a 50
 402 percent confidence level of underrun (p50), then that value (and any p-value such as the p10 and p90 for the range)
 403 from the total distribution can be displayed using an MCS add-in formulae. The outcome p-values can be presented
 404 in tabular form, a frequency diagram (as illustrated in the bottom curve of Figure 5) or cumulative frequency diagram
 405 (s-curve).
 406

407 The example MCS used *trigen* distributions of the low, most likely, and high range factors. The example in Figure 4
 408 assumes that the team’s inputs (and/or the facilitator’s ability to elicit true lows and highs) were optimistically biased
 409 (see RP 66R-11 concerning distributions). [15] The selection of distributions and the various distribution attributes

February 23, 2022

410 applied are assumptions that need to be challenged by the facilitator. Again, this example MCS application is not a
411 recommendation but an illustration of how a variety of MCS approaches is possible.

412

413 MCS Dependency Application

414 MCS best practice requires that correlation be defined between distributions where there is a dependency
415 relationship between them. This is illustrated by the dashed arrows in Figure 5. Correlation can be somewhat
416 addressed outside of MCS math; for example, performing the QRA at the discipline level of costs assumes all detailed
417 items within that discipline behave the same way (i.e., they are 100% correlated). Similarly, the example model
418 combined the productivity & rates (and the quantity & price) for costs through multiplication of their L/ML/H values
419 and only applying the trigen distribution to the resultant L/ML/H product of the multiplication. This multiplication
420 likewise assumes 100% correlation of these drivers. Such base modeling assumptions are often of a questionable
421 nature as they are here. For example, why should all Civil detail items be correlated and why should productivity
422 (hours) and labor rates be correlated?

423

424 Correlation can also be addressed through the MCS add-in formulae. The example model assumes that three sets of
425 item distributions are internally correlated; i.e., the labor item distributions, the bulk material and subcontract item
426 distributions, and the indirect item distributions (major equipment price was assumed to be not correlated to
427 anything). The example does not define correlations between these broad cost categories. For example, civil and
428 piping discipline labor cost are assumed correlated, but direct labor and indirect costs are not. It should be obvious
429 to an estimator that the later assumption is questionable (e.g., if direct labor hours increase, so too will field office
430 indirect costs).

431

432 The last correlations in Figure 5 are between the duration range factor distribution and the cost range factor
433 distributions as appropriate. In the example which has multiple cost range distributions by element, correlations
434 between the cost estimate quantity and hour inputs and duration make sense (more quantity and hours implies
435 longer duration), but correlation between the rates and prices and duration is not as logical.

436

437 *2.2.2. R+EV Model*

438

439 Figure 6 is a snapshot of a simplified R+EV tool model worksheet in Excel®. Note that this is the same tool worksheet
440 as used in the Parametric + EV example in RP 113R-21 with the exception that step 4 carries over the inherent risk
441 from the ranging model rather than the systemic risks from the parametric model. It has been set up to use PDFs
442 and an MCS add-on. In a fully developed tool, there would be more thorough entries, enhanced features such as 3-
443 point probabilities and burn rates, etc. The various user input sections are numbered and described as follows:

444

- 445 1) Enter the base cost estimate and schedule duration.
- 446 2) Enter the critical risks (e.g., one risk is entered for a *Mudslide* in Figure 6).and probability of occurrence (re:
447 section 2.1, step 5) This could be enhanced to 3-point entry and PDF application. Note the inherent risk
448 probability is 100%.
- 449 3) Enter the burn rates (re: section 2.1, step 6) for respective contract/elements. This would usually be
450 enhanced to contain multiple possible burn rate elements/phase/contracts and so on, and the user could
451 select, for each critical risk, which burn rate applies. It could also be enhanced to 3-point entry and PDF
452 application.
- 453 4) This section carries over the cost and duration ranging model outcomes for inherent risks. A trigen PDF has
454 been applied; this is risk #1 in the R+EV tool with MCS.
- 455 5) Finally, enter the critical risk responses (re: section 2.1, step 7) and schedule and cost impacts (re: section
456 2.1, step 8) (only one risk entry area is shown). The mean results of probability x impact are shown. In
457 addition, the sum of the means of all the risks and the total mean project schedule duration and cost are
458 shown.

459

February 23, 2022

460 After running the MCS simulation, the outcome distribution tables at the bottom are populated from which
 461 management may determine contingency and reserves values.

 464 **Figure 6 – Example R+EV Model Integrating Inherent and Project-Specific Risks [[14]; with permission]**

February 23, 2022

3. SPECIAL CONSIDERATIONS FOR HYBRID APPLICATION

The following are considerations for assuring that all critical uncertainties and risks are covered by the combined methods (keeping mind that this tool is not to be used for projects with significant systemic risks) while also assuring there is no redundancy:

Start-up and Commissioning and Other Phasing

The nature of the risk profile for the execution phase often differs from that of the start-up and commissioning (SU&C) phase. The example was focused on the execution phase (sanction through mechanical completion). However, the example for the inherent risk ranging model could be expanded to include a SU&C cost estimate entry. Also, the SU&C duration and risk factors could be added as their own entries with the overall duration outcome being the sum of the sequential execution and SU&C phases. Project-specific risk events during SU&C could then be added to the EV model section. The same approach could be used for other phased risks.

Uncertainties That are Project-Specific

There are risks commonly found in risk registers that are uncertainties ($p=100\%$) but are not inherent risks (i.e., they are identifiable and manageable to some extent). Examples are weather variability and soils condition variability that are not caused by an event (e.g., not a hurricane). The nominal uncertainty from these risk drivers may partly be covered by the team's ranging inputs (e.g., quantity of rock in the soil); however, extreme (critical) condition variability may not be covered in these ranges. For example, assume an analysis was based on 20% of a pipeline trench containing rock; however, the trench may be just one item in a broad civil discipline entry and the trench rock risk may not have received full attention. In this case, the risk that the rock content may range from say 10% to 80% of the trench length could be added as a critical specific condition uncertainty in the EV tool. Note that extreme or critical variation is not an event; i.e., there is 100% probability the rock content will not be exactly 20%. This example risk should be entered as an uncertainty ($p = 100\%$) with a most likely cost impact of 0% (quantity and cost is the same as the base plan) but a low and high reflecting the extreme variability applicable to that right-of-way.

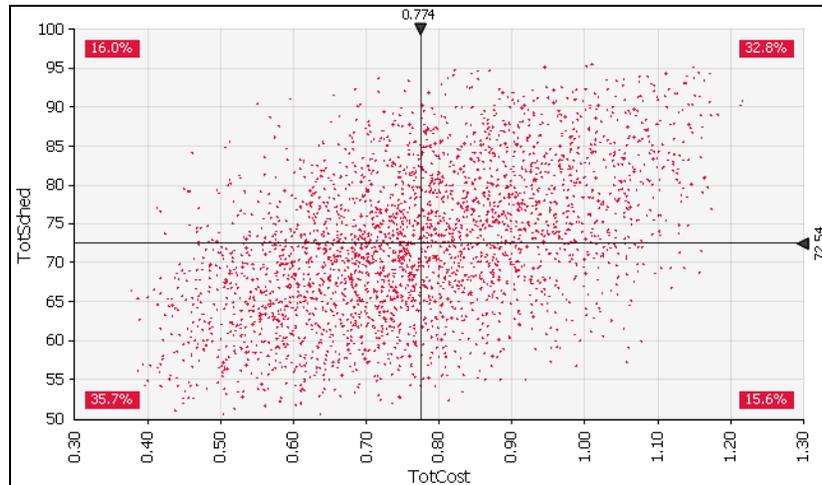

Impacts to Intermediate Milestones

While the EV method cannot examine the impact of risk to the internals of a CPM model, it is capable of assessing impacts to a major intermediate milestone. Perhaps the most common example are projects with seasonality where a harsh winter, monsoons or other condition change puts a premium on completing part of the work prior to the onset of the adverse season (i.e., a phased project). The section on dealing with SU&C describes how the duration uncertainty could be quantified by phase in the ranging model. For risk in the EV model, the phasing approach is described in RP 65R-11. However, in summary, it involves creating a subtotal of the schedule impacts for risk events that occur prior to the seasonal deadline plus that phase's inherent duration risk. This subtotal is made an MCS output that one can review independently of the later phase(s). After running the MCS, a review of this subtotal will provide the distribution of the pre-milestone delay. From that a decision could be made whether to revise the schedule to include an appropriate schedule contingency buffer prior to the intermediate milestone. The R+EV method is quite flexible for addressing various risk analysis situations like this that may arise.

3.1. Note on Joint Confidence Level (JCL) Determination

In 2009, the National Aeronautics and Space Administration (NASA) instituted a policy that certain project budgets were to be based on a "joint cost and schedule probabilistic analysis" with budgets to reflect a "percent probability that the project will be completed at or lower than the estimated amount AND at or before the projected schedule." [16] NASA calls this the joint confidence level or JCL. In NASA practice, the JCL is based on the cost-loaded CPM-based risk analysis method. However, CPM modeling is not required for JCL; the hybrid P+EV method integrates cost and schedule and supports JCL determination. Figure 7 is an example cost and schedule MCS output scatterplot (in

514 this case using Palisade @Risk® software) from the R+EV hybrid method. Note that RP 65R-11 also has an example
515 JCL plot; in that case resulting solely from the project-specific risks.

519

520 **4. COMPARISON OF THE R+EV HYBRID METHOD TO RP 40R-08 PRINCIPLES**
521

522 RP 40R-08, *Contingency Estimating – General Principles*, provides objective principles against which one can assess
523 the suitability of a contingency estimating method [17]. The following are the RP’s general principles that any
524 methodology developed or selected for quantifying risk impact should address:
525

- 526 • Meet client objectives, expectations and requirements.
- 527 • Part of and facilitates an effective decision or risk management process (e.g., TCM).
- 528 • Fit-for-use.
- 529 • Starts with identifying the risk drivers with input from all appropriate parties.
- 530 • Methods clearly link risk drivers and cost/schedule outcomes.
- 531 • Avoids iatrogenic (self-inflicted) risks.
- 532 • Employs empiricism.
- 533 • Employs experience/competency.
- 534 • Provides probabilistic estimating results in a way the supports effective decision making and risk
535 management.

536
537 Table 1 summarizes how the R+EV hybrid method performs in respect to the principles.
538

539

First Principles	Hybrid R+EV Method Characteristics
Meets client objectives and requirements	Realistic and practical for projects without significant systemic risks. Can be used for estimates and schedules of any quality at Class 3 or better. It is highly customizable.
Part of a risk and decision management process	The method is risk driven supporting risk management. The EV method is an elaboration of the risk matrix (no conceptual discontinuity between qualitative and quantitative assessment).
Fit-for-use	Can be used on any estimate or schedule of any quality and can be applied using common software (i.e., spreadsheets with MCS add-on) that can be customized.
Starts with identifying risk drivers	It does not address systemic risks well which limits its use to better-defined projects with lower complexity and technology. Elements of inherent uncertainty can be assessed in the ranging method and critical project-specific risks are individually assessed.
Links risk drivers and cost/schedule outcomes	Driver-to-outcome linkages are explicit for project-specific risks and uncertainties (albeit not suitable for high systemic risk projects). The EV method focuses on risk response planning incl. cost/schedule trading. Cost and schedule inherent uncertainty can be correlated. Method supports JCL.
Avoids iatrogenic (self-inflicted) risks	Ranging can be done in a way that minimizes correlation challenges (e.g., range subtotals or similar cost items). The EV method only quantifies critical project-specific risks which also minimizes MCS correlation challenges.
Employs empiricism	While it is optimal to use historical data in the ranging and EV methods, good data is generally not available at most companies. The method is largely dependent on the elicitation skills of the facilitator to assure experiences of the team are brought to the table.
Employs experience /competency	As with all methods, requires experienced risk analysis facilitation. Not using CPM, the EV method requires experienced planner/scheduler input.
Provides probabilistic estimating results	All integrated methods covered by AACE RPs produce probabilistic outcomes. Supports JCL evaluations.

541
542
543

Table 2 provides a strength/weakness evaluation of the P+EV hybrid method.

Strengths	Weaknesses
<ul style="list-style-type: none"> Integrates cost and schedule analysis Allows changes to schedule logic due to risks to be included without the complexity of branching in CPM Ranging leverages team’s knowledge of the estimate and schedule basis Explicit risk-impact linkage for project-specific risks Fairly simple, flexible and widely used method can be applied in a myriad of ways (e.g., various levels of detail for ranging) EV method addresses risk response (i.e., cost/schedule trading) 	<ul style="list-style-type: none"> Ranging is highly subjective and can be prone to team bias No explicit empirical basis Does not address significant systemic risks; hence not applicable to early phases (e.g., not for Class 10, 5 or 4) Not being CPM model based, requires more skilled/intuitive scheduling assessment The EV method does not encourage the use of quality planning and schedule methods Does not support evaluation of the risks to intermediate schedule milestones as directly as CPM-based methods.

546 **5. SUMMARY**

547
548 This RP provides guidance to practitioners in developing or selecting appropriate methods for their situation with
549 the understanding that no one method is best for quantifying all types of risk. This RP integrates cost and schedule
550 risk analysis (and supports JCL) using a hybrid approach. It documents the steps to combine the ranging and expected
551 value methods covered by other RPs in detail. It provides an example using a demonstration toolset. It also
552 documents situations where a hybrid approach requires or may benefit from special considerations.
